ABSTRACT

Regarding to the influence of chloride and fluoride ions on the corrosion resistance, the electrochemical behavior of Ti alloys has been deeply studied. In this work, the main goal was to investigate the electrochemical behavior of cp-Ti and Ti-Mo alloys containing 6, 10 and 15 wt% of Mo concentrations. All the samples were immersed in different solutions, such as 0.15 mol L⁻¹ Na₂SO₄, 0.15 mol L⁻¹ Ringer, 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF and 0.036 mol L⁻¹ NaF. Simulating the commercial fluorinated gels, the NaF solutions naturally-aerated were prepared with 1450 ppm of fluoride ions. The electrochemical techniques applied in this work were the open-circuit potential, cyclic voltammetry, besides the technique for chemical identification, which was X-ray photoelectron spectroscopy. The formation and growth of TiO₂ and MoO₂ were identified, without pitting corrosion. The electrochemical stability and the corrosion resistance of the Ti-Mo alloys decreased in the solutions containing chloride and fluoride ions, with an appreciative decrease especially in the fluorinated medium. The Ti-Mo alloy with higher Mo content concentration was the material with higher corrosion resistance. Therefore, it is a promising candidate as a biomaterial, once the osseointegration needs a satisfactory corrosion resistance for being achieved.

Keywords: Thin Films; Corrosion Resistance; Metal and Alloys; Photoelectron Spectroscopies

1. Introduction

It is well known that titanium and its alloys present a high corrosion resistance in severe corrosive environments, besides an excellent biocompatibility. During the titanium alloy exposure to the halide-containing electrolytes, the oxide films spontaneously developed are susceptible to the pitting corrosion. It is a localized corrosion that is very harmful because it causes a corrosive attack that penetrates into the matrix of the alloy and makes the mechanical properties weaker. Besides the good corrosion resistance of the titanium alloys, their wide application is explained by their biocompatibility and mechanical properties as low Young's modulus, high yield and tensile strength^[1,2].

The corrosion phenomena is classified in pitting, galvanic coupling, crevice corrosion, fretting corrosion

and corrosion fatigue, which are observed in conventional implants, such as implants made of stainless steel, Co-Cr alloys or commercial pure Titanium (cp-Ti), and Ti-6Al-4V^[3]. The passivation and re-passivation prevent or inhibit that phenomena in the metallic implant materials, controlling the initiation of corrosion and the enhancement of the ability of self-healing of the surface^[4]. The protection features of that oxide films formed spontaneously on the material oxide surface are improved by adding Mo to pure Ti.

Under the norm ASTM F 2066, the Ti-15Mo alloy was approved to be applied in devices as implants for humans^[5]. According to Rodrigues *et al.* (2015), a stable passive oxide film was formed on the Ti-15Mo alloy surfaces, which were exposure to naturally-aerated solutions containing chloride and fluoride ions that caused a decrease in corrosion resistance^[6]. The literature

describes the increase of the corrosion potential and polarization resistance, and the decrease of the oxidation tendency when the Mo contents are added into the Ti alloy in sequence cp-Ti > Ti-6.5Mo > Ti-8.5Mo > Ti-10Mo^[7].

The aim of this work is to develop surface layers with enhanced stability against to the localized corrosion processes. Through the X-ray electron spectroscopy, the structures of TiO₂ and MoO₂ were characterized. The corrosion resistance was evaluated for the behaviors of cp-Ti and Ti-Mo alloys containing 6, 10 and 15 wt% of Mo in media with chloride and fluoride ions. The solutions were prepared to simulate the commercial fluorinated gels that contain 1450 ppm of fluoride ions^[8]. In this work, the pH of the solutions was kept as 7, avoiding the formation of TiF₃, TiF₄ and TiOF₂ which could dissolve the passive films. The addition of Mo improved the passivity and the corrosion resistance of the Ti alloys, observing their electrochemical behavior through the electrochemical techniques, such as open circuit potential and cyclic voltammetry^[9].

2. Materials and methods

The samples of Ti-Mo containing 6, 10 and 15 wt% of Mo were prepared using arc-melting furnace under ultra-pure argon atmosphere, whose procedure is well described in the literature^[10]. Both TiO₂ and MoO₂ passive films were analyzed by XPS.

The electrochemical performances were conducted in a standard three-electrode cell. The three-electrode were built with 0.44 cm² of exposure area in the working electrode, a platinum mesh as a counter electrode and a SCE as reference. Those measurements were performed in the naturally-aerated solutions: 0.15 mol L⁻¹ Na₂SO₄, 0.15 mol L⁻¹ Ringer, 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF and 0.036 mol L⁻¹ NaF. The 0.15 mol L⁻¹ Ringer solution was composed of 8.610 g L⁻¹ NaCl, 0.490 g L⁻¹ CaCl₂ and KCl 0.300 g L⁻¹.

The experiments with the working electrodes (cp-Ti, Ti-6Mo, Ti-10Mo and Ti-15Mo) were conducted at 25 °C. The working electrodes were polished with 600 grade silicon carbide paper and rinsed with distilled and deionized (Milli-Q®) water. Both potentiostat/galvanostat Solartron Electrochemical Interface, mod. SI 1287, and Solartron Instruments HF Frequency Response Analyser,

mod. SI 1255, were used to measure the open circuit potential and cyclic voltammetry values. The open circuit potential measurements were carried out on freshly-polished samples, in naturally-aerated aqueous electrolytes solutions already mentioned, immediately after polishing. These values were recorded after 1 h, and repeated three times in order to verify the reproducibility of the technique. The cyclic voltammetry analyses were set up at a potential in the hydrogen evolution region (-0.8 V vs. SCE) by scanning at 50 mV s⁻¹ towards more positive potentials up to 8.0 V (SCE), when the scanning was reversed towards to the initial potential. Either the open circuit potential graphs or cyclic voltammograms were obtained for cp-Ti and Ti-Mo containing 6, 10 and 15 wt% of Mo, which were immersed in all the referred electrolytes.

After 1 h of Ti-Mo alloy immersion in the referred solution and the application of the electrochemical impedance spectroscopy (EIS), it was used a spectrometer UNI-SPECS UHV for the X-ray photoelectron spectroscopy measurement in order to analyze the Ti-Mo chemical structure. The line Mg was used (hν = 1,253.6 eV), and the energy step of the analyzer for high resolution spectra was set to 10 eV. The composition of the surface layer (~ 3 nm) was determined with accuracy of ±10%, and the error of the peak positions was ±0.1%.

3. Results and discussion

The cp-Ti was used as a control in the electrochemical measurements, where the Ti-6Mo, Ti-10Mo and Ti-15Mo alloys behaviors were also performed in different electrolytic solutions simulating the naturally-aerated medium.

3.1 Open circuit potential (E_{oc})

The time, when the oxide film was formed on the alloy surfaces, was measured by the spontaneous process of E_{oc}, showing the protection of the metal and metal alloys against the corrosion as long as the potential was raised.

The curves of E_{oc} variation versus time were demonstrated for cp-Ti, Ti-6Mo, Ti-10Mo and Ti-15Mo, analyzed in solution as Na₂SO₄, Ringer, Ringer plus NaF and NaF, which are depicted in **Figure 1 (a)**, **Figure 1 (b)**, **Figure 1 (c)** and **Figure 1 (d)**, respectively.

Figure 1; E_{oc} as a function of time for cp-Ti and Ti-Mo

alloys (Ti-6Mo, Ti-10Mo and Ti-15Mo) in solutions of (a) 0.15 mol L⁻¹ Na₂SO₄, (b) 0.15 mol L⁻¹ Ringer, (c) 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF, and (d) 0.036 mol L⁻¹ NaF.

The addition of Mo to cp-Ti and their alloys increased the protective properties of the metallic oxide, observed by the potential increased in the beginning of the measurements and stop raising after approximately 10 min. The stable potentials in the open-circuit measurements are related to the formation and thickening of the oxide film on the patterns surfaces. All the samples presented the same behavior, showing the tendency to form a passive film, demonstrated by the shift of the E_{oc} to more positive direction with the time. Either in Ringer or fluorinated solutions, the E_{oc} for Ti-15Mo is more positive than that for cp-Ti and other Ti alloys containing different Mo concentrations. This is explained by the Mo contributions in the formation of the oxide film^[6,11]. There was a decrease of E_{oc} in the fluorinated solution compared with the values obtained under the Ringer medium, explained by the corrosion resistance decrease, especially of the cp-Ti, caused by the fluoride ions which attack more significantly the oxide film. The values potentially less negative in Ringer meant the anodic passivation which improved the corrosion resistance of the Ti-15Mo alloy^[12].

3.2 Cyclic voltammetry (CV)

The cyclic voltammograms were performed for investigating the dissolution kinetics of the cp-Ti and Ti-Mo alloys surfaces modification. The cyclic voltammograms, observed in **Figure 2**, were recorded for the Ti-6Mo, Ti-10Mo and Ti-15Mo, which were exposed in solutions as Na₂SO₄, Ringer, Ringer plus NaF and NaF mentioned before. There were formation and growth of the anodic oxide film in the region a during the increase of the anodic current density, and the passivation of the materials in the region b. It was reached a current plateau and there was no transpassivation in potentials up to 8 V^[6,13-14].

Figure 2; Cyclic voltammograms for cp-Ti and Ti-Mo

alloys (Ti-6Mo, Ti-10Mo and Ti-15Mo) in solutions of (a) 0.15 mol L⁻¹ Na₂SO₄, (b) 0.15 mol L⁻¹ Ringer, (c) 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF, and (d) 0.036 mol L⁻¹ NaF, at a scan rate of 50 mV s⁻¹. Regions of a and b are related to be the formation/growth of the anodic oxide film and the passivation of Ti materials, respectively.

There was also no pitting corrosion in all the Ti-Mo alloys exposed in the different solutions during the potential scans, suggesting their high resistance even in the presence of fluoride ions, which did not avoid the formation of the passive film probably due to the small amount of HF in the solution, nevertheless these ions can dissolve the passive film due to the formation of TiF₃, TiF₄ and TiOF₂^[13], expressed in the (1), (2) and (3) reactions:

At the scan of 50 mV s⁻¹, the cyclic voltammograms demonstrated a passive plateau, which had a constant current density up to a potential of 4 V correspondent to the thickening of the oxide film, indicating the growth of anodic oxide film of TiO₂ and its thickness linearly increasing with the applied potential. There was an improvement of the resistance against the corrosion processes in the Ti-15Mo alloy, especially in the media of Na₂SO₄. The values of the current density in the positive scan increased in the presence of the chloride and fluoride ions, indicating that there was a current resistance reduction of the patterns immersed in the related media. The literature has described a deleterious influence of these sorts of ions in the corrosion resistance behavior of Ti alloys: at high concentrations of fluoride ions, for instance, up to 10000 ppm, in a range of pH between 7.2 and 3.2, there is a losing of the Ti alloys corrosion resistance properties. It is a noticeable impact when the gels and solutions contain a concentration of fluorides relatively high in order to prevent dental caries^[14-16].

Observing all the cyclic voltammograms, it was realized that there was a rapid decrease of the current density to values close to zero during the reverse scan, without the reduction of the passive film. The current density started increasing at 4 V, which meant the existence of a parallel reaction of water oxidation and

release of O₂. According to the Pourbaix diagram, the oxidation reactions of water above 1.2 V is enabled to be occurred, therefore, explaining that release of O₂ close to 4 V^[6,15].

3.3 X-ray electron spectroscopy (XPS)

The oxide compositions formed under the Ti-Mo alloys surfaces were identified by the XPS technique, which showed the surfaces of the anodized samples containing TiO₂ and MoO₂^[12]. The thickness of that oxide films was also identified after the EIS. The XPS spectra of high resolution are visualized in **Figure 3** for the Ti-15Mo alloy after the EIS application under the solutions of (a) 0.15 mol L⁻¹ Na₂SO₄ and (b) 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF.

Figure 3; XPS spectrum with high resolution of TiO₂ for Ti-15Mo after the EIS application under the solutions of (a) 0.15 mol L⁻¹ Na₂SO₄ and (b) 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF.

The TiO₂ peak appeared at 458 eV, correspondent to the Ti 2p. This peak was observed for both Ti-15Mo alloy that were kept, after the EIS application, under the solutions of 0.15 mol L⁻¹ Na₂SO₄ and 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF. The passive film was formed. The ratio between the Ti and Mo concentrations were higher as 7.6% in the medium of Cl⁻ ions, and the least of 4.6% in that containing solely the F⁻ ions, which attack the alloy in the passive regions, even it was formed spontaneously under the alloy surface^[6]. Investigating the sorts of the passive film grown and formed on the Ti-Mo alloy surfaces, the Ti-15Mo was taken into account to be observed, once the resistance existent against corrosion processes was higher in that 15 wt% of Mo concentration. After the EIS application

applied on the surface of Ti-15Mo alloy, which was immersed in the solution containing both of chloride and fluoride ions simulating the physiological media, the presence of another film as MoO₂ was investigated on the surface of the same passivated patterns. In the XPS spectrum with high resolution represented in **Figure 4**, it is also likely to observe the peaks of Mo and its molybdenum oxide as MoO₂: (a) Mo 3d_{5/2}, (b) Mo 3d_{3/2}, (c) MoO₂ 3d_{5/2}, and (d) MoO₂ 3d_{3/2}.

Figure 4; XPS spectrum with high resolution of Mo 3d and MoO₂ 3d for Ti-15Mo after the EIS application under the solution of 0.15 mol L⁻¹ Ringer plus 0.036 mol L⁻¹ NaF: (a) Mo 3d_{5/2}, (b) Mo 3d_{3/2}, (c) MoO₂ 3d_{5/2}, (d) MoO₂ 3d_{3/2}.

It can be concluded that the obtained TiO₂ and MoO₂ passive films were on the cp-Ti and Ti-Mo alloys surfaces, without unoxidized metal, the same behavior found into the Ti-15Mo which used electropolishing and anodic passivation processes described in the literature^[12].

It is known that the Mo has high solubility in Ti and larger atomic radius, causing the lower Young's modulus, for instance, in the Ti-12Mo-13Nb. By this way, the presence of larger atomic radius reduces the binding force of the Ti lattice, expanding the unit cell volume^[17]. The MoO₂ is the most stable film of Mo, inert and insoluble in water and alkaline media, forming solid solutions with TiO₂. On the Ti-Mo alloy surface, it is the first barrier formed, therefore, the first layer attacked by the aggressive ions, explaining the least amount of Mo. The second barrier formed spontaneously is the TiO₂ thin film. Despite of the fact there was a decrease of the TiO₂ and MoO₂ film thicknesses, there was still alloy surface protection, observed by the E_{oc} and CV values^[6,18].

According to the Sun *et al.* (2012), the signals in the XPS spectrum with high resolution at 230.1 and 233.3 eV can be attributed to the presence of MoO₂ 3d_{5/2} and MoO₂ 3d_{3/2}, respectively^[19,20]. And the signals of Mo 3d_{5/2} and Mo 3d_{3/2} are located at 227.3 and 230.6 eV, respectively^[21]. It is realized that the band intensity of the Mo 3d correspondent to the MoO₂ is much lower than that one related to the Ti 2p correspondent to the TiO₂ because the main component of the passive film is the TiO₂ in both cp-Ti and Ti-Mo alloy, once the concentration of Ti element is higher than that of Mo^[22].

4. Conclusions

A decrease of the corrosion resistance occurred in both the cp-Ti and Ti-Mo alloys when they were immersed in the solutions containing fluoride and chloride ions. There were formation and growth of passive films of TiO₂ and MoO₂ without pitting corrosion. Even the corrosion resistance was lower in the presence of fluoride ion, explained by its more aggressive attack to the surface passivated, there was the protection of all the cp-Ti and Ti-Mo alloys against the corrosion, increasing with the Mo content concentration.

Author Contributions

The authors of this paper, A V R and A C G, contributed to the academy and scientific research with the study of the corrosion protection of cp-Ti and Ti-Mo alloys. Evidences of materials corrosion resistance improvement were proved through their electrochemical performance changing, which was took into account the authors' knowledge about the electrochemical techniques, such as open-circuit potential and cyclic voltammetry. The X-ray photoelectron spectroscopy was also applied in this work for helping the identification of the sorts of films, TiO₂ and MoO₂, formed on the materials surface after these ones were kept into different electrolytic solutions simulating the naturally-aerated medium. The alloys passivation was improved with the raise of Mo content concentrations. Even in the presence of aggressive environment, the corrosion resistance of the materials, in special Ti-Mo alloys, was raised without pitting corrosion occurrence.

Conflict of Interest

No conflict of interest was reported by the authors.

Acknowledgments

The authors express their sincere acknowledgments

to N.T.C. Oliveira for providing the Ti-Mo alloys by using an arc-melting furnace under an ultra-pure argon atmosphere. Besides the Institute of Chemistry of UNESP University that supported this work with equipments and lab space.
